Operating Systems	3
Topics	3
Course Information	3
Textbooks / Resources	4
Readings	4
Lectures	4
Lecture One - Introduction to Operating Systems	4
Lecture Two - Processes and Threads (2.1, 2.2)	9
Lecture Three - Processes and Threads (2.3, 2.4, 2.5)	17
Lecture Four - Deadlocks, Starvation and Thread Patterns	19
Lecture Five - Signals and Pipes	20
Lecture Six - Sockets	23
Lecture Seven - Socket Coding	30
Lecture Eight - Scheduling	31

Operating Systems

These notes are designed to be used in conjunction with the slide sets provided in the course, the slides will be more helpful for use in the labs *due to including code examples*, these notes will provide a good outline for studying for the final exam.

Topics

Lectures 1-8: Multiprocessing

Course Information

The course covers core topics.

- Introduction to operating systems
- Processes and Threads
- Pipes
- Sockets
- Deadlocks
- Files and Directories
- Input/output
- Memory management - Caches
- Memory management - Virtual memory
- Virtualisation

Grade structure

Standard Computer science policy applies

- Average 50% over all assessment items
- Average at least 45% on all invigilated assessment items

Grading structure for course

- Lab Test (20%)
- Assignment (20%)
- Lab quizzes (10%)
 - Weekly Quiz Assessments
- Final Exam (50%)

- Closed book and no calculator
- Cheat sheet Double sided A4

Textbooks / Resources

- Modern Operating systems - Andrew Tanenbaum
- Xv6 - Online shorter method, lots of examples

For information on these resources see the first lecture slides

Readings

Lectures

Lecture One - Introduction to Operating Systems

The beginning of computing

- Called the Analytical engine
- Charles Babbage 1834-1871
- Digital, programmable, *Turing complete*
- Punch card IO
- Unable to be engineered
- Would be very slow
- Ada Lovelace - worlds first programmer

1st Generation computers

In 1945 we moved on to hard-wired machines. These were just a plugged set of wires.

2nd Generation computers

Operating systems started to appear when systems were designed to be programmable, this came with programmed batch systems, they operated with one job at a time and had storage, this is the initial life of an operating system.

3rd Generation computers

- Multiprogramming
 - the ability to run multiple jobs at once
- First real operating systems

- MULTICS/Unix/Linux, VMS and others

This brought the first initial need for security and segregation between users on the same machine.

4th Generation computers

This is the first view of **personal computers**, bringing the **BASIC** interpreter using Machine code, complexity hidden from the user, one program could be held in memory.

Usually had ~8 kb of memory to run the entire operating system.

Eventually got a GUI, use of mouse and the initial real world of what we call computers, could also store multiple applications in memory at once.

Then finally, we have modern day computers

- Personal
- Multiple applications at once
- Modern OS, (*Linux, MacOS and Windows*)

5th Generation computers

Wearable devices, quantum computing and further AI development, we are not there yet!

What is in a computer?

- CPU
- Memory
- Video Controller
- Keyboard Controller
- Optical disk controller
- Hard disk controller

This is even a simplistic model, a computer really looks like this:

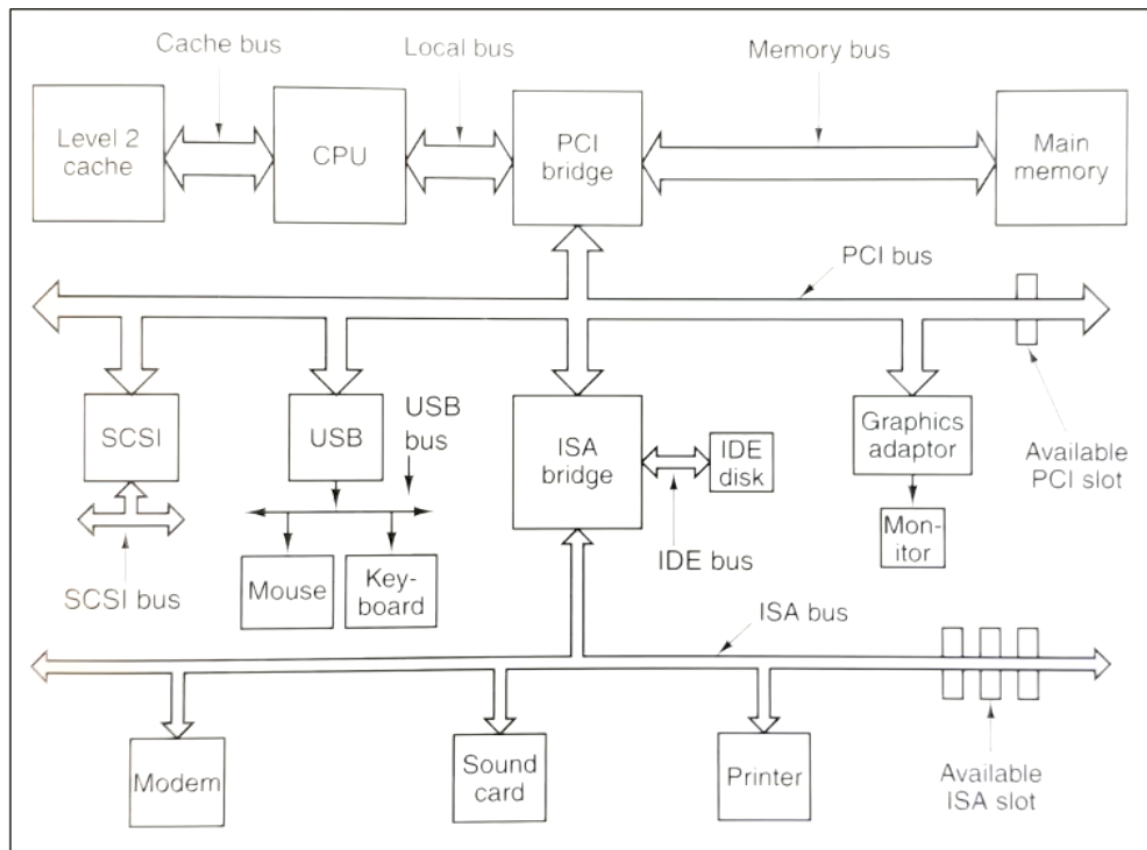

Figure 1: Computer Model

It is extremely difficult to have to write to all sectors of this without knowing its exact structure and expected input. This means that we need some interface to handle this for us. Hence, **operating systems**.

Storage hierarchy

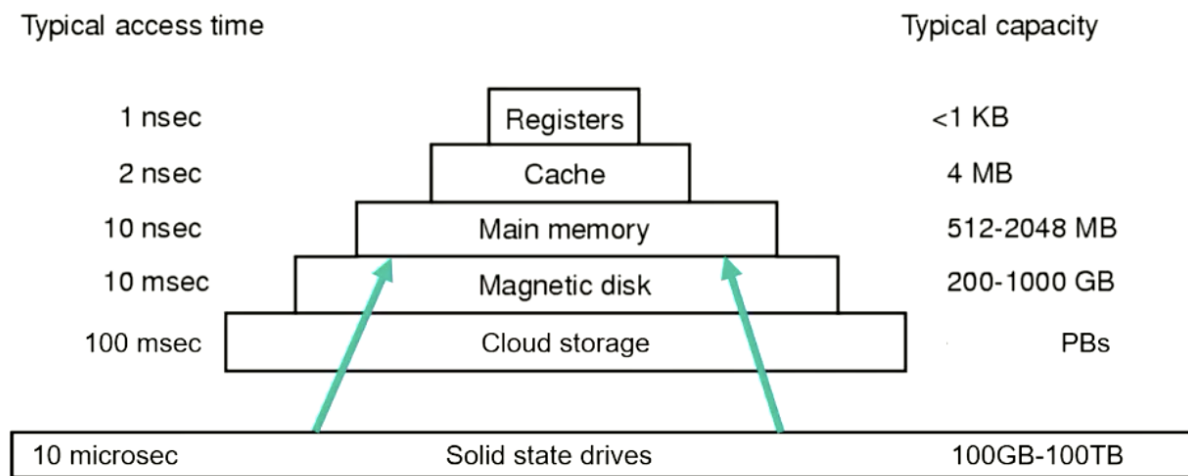

Figure 2: Storage hierarchy

In order for the operating system to work, it needs to have some method of handling storage, and knowing where we are allowed to write to, and have some method of creating an interface or abstraction to solve writing issues.

What is the main purpose of an operating system?

- Virtualization (sharing users)
 - Time (CPU)
 - Space (memory)
- Concurrency
- Persistence (I/O)
- Protection
- Hides complex details
- Protects the machine from malicious code

Core OS concepts

These will be expanded throughout the lectures

- Processes
- System calls and kernel mode
- Address spaces
- Files and IO
- The shell

Typical process model

- Processes are normal, sequential code
- The scheduler decides what runs and when
- Alternative cooperative models exists

OS API: System calls

Process management	
Call	Description
<code>pid = fork()</code>	Create a child process identical to the parent
<code>pid = waitpid(pid, &statloc, options)</code>	Wait for a child to terminate
<code>s = execve(name, argv, environp)</code>	Replace a process' core image
<code>exit(status)</code>	Terminate process execution and return status
File management	
Call	Description
<code>fd = open(file, how, ...)</code>	Open a file for reading, writing, or both
<code>s = close(fd)</code>	Close an open file
<code>n = read(fd, buffer, nbytes)</code>	Read data from a file into a buffer
<code>n = write(fd, buffer, nbytes)</code>	Write data from a buffer into a file
<code>position = lseek(fd, offset, whence)</code>	Move the file pointer
<code>s = stat(name, &buf)</code>	Get a file's status information
Directory and file system management	
Call	Description
<code>s = mkdir(name, mode)</code>	Create a new directory
<code>s = rmdir(name)</code>	Remove an empty directory
<code>s = link(name1, name2)</code>	Create a new entry, name2, pointing to name1
<code>s = unlink(name)</code>	Remove a directory entry
<code>s = mount(special, name, flag)</code>	Mount a file system
<code>s = umount(special)</code>	Unmount a file system

Figure 3: System Calls

These really work because the user has no direct access to the low level routines

- OS runs in kernel mode with higher privileges
- User mode system calls execute TRAP instructions
- Hardware looks up the **Trap table** to find address

Address spaces

Modern operating systems have **Virtual Memory**

- Multiple programs in memory at once
- Idle memory can be paged and swapped to disk
- Give an illusion of unlimited memory (*at a price*)

Sample exam question

Which of the following is NOT an operating system?

- Linux
- Windows
- Android - NOT
 - Is using Linux kernel
- ROS - NOT
 - Is using Linux kernel
 - Is a set of libraries to use with an OS to make system calls
- MacOS
- DOS
- iOS
- Arduino - NOT
 - Is a package

Lecture Two - Processes and Threads (2.1, 2.2)

NOTE: See lecture slides in order to find code examples of using threads and processes

Processes Program counter

One program counter for each process, this allows us to keep processes independent and sequential, this is the foundation of **multiprogramming**, the timer will interrupt a process and switch when its allocated time frame is done.

This is an example of **Pseudo parallelism**

Interrupt process switch

1. Hardware stacks program counter, etc.
2. Hardware loads new program counter from interrupt vector.
3. Assembly language procedure saves registers.
4. Assembly language procedure sets up new stack.
5. C interrupt service runs (typically reads and buffers input).
6. Scheduler decides which process is to run next.
7. C procedure returns to the assembly code.
8. Assembly language procedure starts up new current process.

7

Figure 4: Process switching - Interruption

This is building up the stack

What is the stack?

The stack is going to hold the context of what I am doing, it is a LIFO representation of all the local variables, function calls and procedure calls.

This will be talked about further later

Process Creation and Termination - Linux

Creation

1. System initialization
2. Process creation system call
3. User request to create a new process (shell)
4. Initiation of a batch job

Termination

1. Normal exit *voluntary*
2. Error exit *voluntary*
3. Fatal error *involuntary*
4. Killed by another process *Involuntary*

Linux Process Hierarchy

- Linux processes are a tree like structure of daemons and foreground processes
- All processes belong to a parent *except the init process*
 - Process group receives all signals from the creator
- Running a program starts a new process
- Windows has no concept of process hierarchy
 - Process is independent of its creator
- Each process has a process table
 - we will need to save this table in order to store state of a specific process
 - These are called process control blocks (PCB's)

Create process (Linux) – fork()

```

5  int main(int argc, char *argv[]) {
6      printf("hello world (pid:%d)\n", (int) getpid());
7      int rc = fork();
8      if (rc < 0) {
9          // fork failed
10         fprintf(stderr, "fork failed\n");
11         exit(1);
12     } else if (rc == 0) {
13         // child (new process)
14         printf("hello, I am child (pid:%d)\n", (int) getpid());
15     } else {
16         // parent goes down this path (main)
17         printf("hello, I am parent of %d (pid:%d)\n",
18                rc, (int) getpid());
19     }
20     return 0;
21 }

```

Get my process ID

Child process is a *clone* of its parent

```

hello world (pid:29146)
hello, I am parent of 29147 (pid:29146)
hello, I am child (pid:29147)

```

(Order may vary!)

11

Figure 5: Create Process

In the above block of code, the `fork()` function is being called to create our process. We then can see our process ID and the process is now a *clone of its parent* at the point of creation.

The wait() function

- We can use wait in order to wait for any process to be stopped, we can also use `waitpid()` in order to check if a single process has stopped, this can be useful to detect crashes and log exits.

The exec() function

We can use the `exec()` to run a new process as a child of the current process.

This is extremely useful for re-directing output, for logging, helpful output and more versatile output to play with.

Process summary

- A process is an independent resource group running a single program

- Unix: all processes are created and owned by a parent
- Forking a new process creates a clone of the parent *including the same program counter*
- Exec*(file...) replaces the current program context with the new program file contents
 - Operations such as redirecting and piping output can be run before the program loads
- The code in a process runs sequentially
 - or, does it???

Why concurrent applications?

- Allows parallelism of independent operations in a single program *that share common data*
- Example: word processor (basic):
 - Task 1: respond to user input (updating model)
 - Task 2: reformat document when model changes
 - Task 3: save periodically to disk
 - Task 4: spell check

Concurrent applications will allow us to treat these as all independent tasks, treating these as processes will run into issues as they do not know when other processes have completed tasks this means we will have to use signals every time that we want to achieve something that requires information from another process. *we can do this, and will, but not today.*

We can use a **finite state machine**

DIY concurrency: finite state machine

- Keeps track of requests and switches work when they “block”
- Cycles through jobs
 - Updating job statuses
 - Performing work
- Requires *non-blocking system calls* to be available

16

Figure 6: DIY Concurrency

Instead of doing this with a finite state machine, we can use **Threads**

Threads Threads have their own thread table, this is called a process data space, multiple threads can access the same process data space.

- Threads have access to process data space
 - but not direct access to each other
- The thread is not a clone, it runs a callback function
- Waits for completion
- The order on the stack can vary as each thread has its own stack

Threads versus processes

```
main()
{
    pid_t childPid = fork(); // Process
    if (childPid == 0)
        printf("I am the child process\n");
    else
        printf("I am the parent process\n");
}
```

```
main()
{
    pthread_t childId;
    pthread_create (&childId, NULL, ChildCode, NULL); // Thread
    printf("I am the parent thread\n");
}

void* ChildCode (void* arg) { printf("I am the child
    thread\n"); }
```

20

Figure 7: Threads vs Processes - code example

POSIX threads API

- Standard runtime library calls for managing threads:
 - `pthread_create`
 - * creates a thread to execute a specified function
 - `pthread_exit`
 - * Causes the calling thread to terminate without the whole process terminating
 - `pthread_kill`
 - * sends a *kill* signal to a specified thread.
 - `pthread_join`
 - * Causes the calling thread to wait for the specified thread to exit. Similar to `waitpid()` for processes
 - * Waits for the child thread to finish

- * Generated by `pthread_join()` from `pthread_exit()` after the thread has exited
- * Need to be very careful about how you return values from a thread
- * We need to return to the heap not the stack in order to make it global, note this will need to be freed
- `pthread_self`
 - * Returns the callers identity *The thread ID*
- `pthread_yield`
 - * Yields the CPU to another thread
- There are many more calls available in the **man pages**

Threads vs Processes

- Access to the same data makes communication easy
- Very fast to create, can be fast to switch
- Possible performance gains from switching within a possible process
- Can be spread across CPU's for further parallelisation
- Difficult to write and debug the code
 - Ordering issues
 - Data access issues

How are threads and processes implemented?

- Threads and processes can be implemented both at the User level and in the kernel.
 - Threads and processes in the kernel are not run by the scheduler, nor handled in the user space

Implementation options

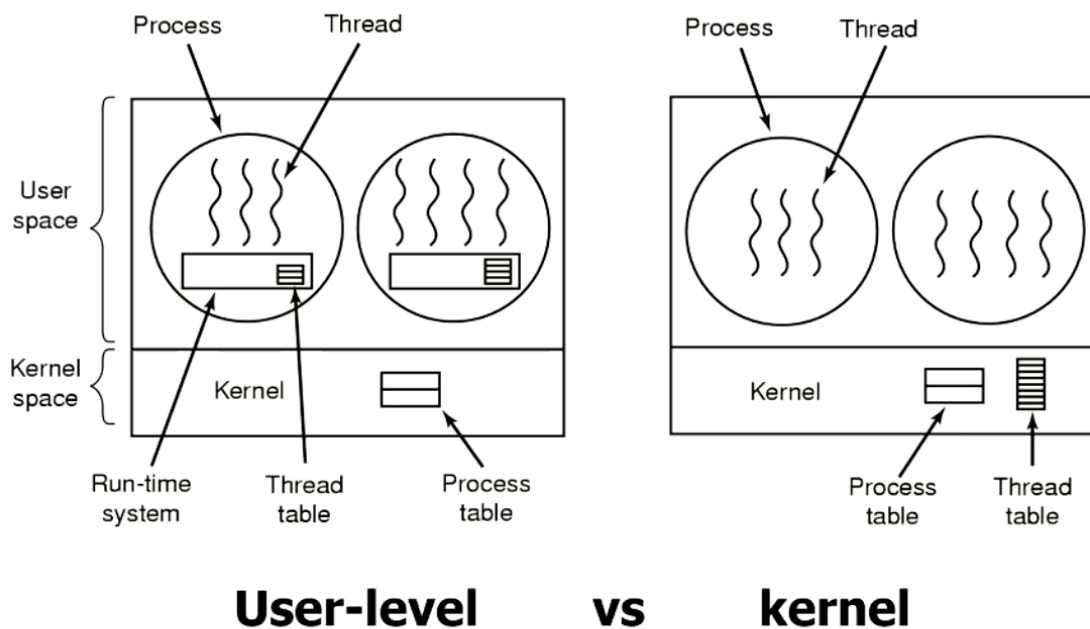

Figure 8: User-level vs Kernel implementation

Lecture Three - Processes and Threads (2.3, 2.4, 2.5)

Critical Regions

- Mechanism to provide “mutual exclusion” of critical regions
- No two processes in critical region at the same time
- No assumptions about CPU's

Mutual Exclusion

Four conditions to provide workable mutual exclusion:

- No two processes simultaneously in critical region
- No assumptions made about speeds or numbers of CPU's
- No process running outside its critical region may block another process
- No process must wait forever to enter its critical region

Non-solutions, these violate the above conditions

1. Blocking process disables interrupts on CPU
2. Lock variable, updated just before entering the critical region
3. *strict alternation* (lecture slide 6)
 - Loops on block
 - What happens if one process is much slower than the other, or halts?
 - Which condition is violated?

4. *Peterson's solution*

- Each process hands off the “turn” to the other process
- Blocking occurs in the critical region only
- Still “busy waiting” - prone to CPU “priority inversion problem”
- Some systems reorder memory access
 - Simpler solutions exist in hardware, this system is sometimes built into the CPU

Block on wait - mutual exclusion

- Sends signals between process to wakeup the other process, we then sleep our own process
 - Uses a counter, when it reaches 0, it sleeps itself and parses a signal to the other process
- What happens when a wakeup signal is sent to a process that isn't asleep?
 - This is because we are assuming that this is an atomic operation, however it is not,

Semaphores - An actual used solution to solve mutual exclusion

Atomic operations to raise or lower their value

NOTE: fix this up from the slides

Implementation:

- Setting lock by decrementing semaphore
- Releases by incrementing semaphore

POSIX thread implementation

- Mutex atomically locks/unlocks
 - Uses for access to critical region

Operation	POSIX Threads
Create condition variable	<code>pthread_cond_init()</code>
Destroy condition variable	<code>pthread_cond_destroy()</code>
Block waiting for signal	<code>pthread_cond_wait()</code>
signal and wake one thread	<code>pthread_cond_signal()</code>
signal and wake all threads	<code>pthread_cond_broadcast()</code>

NOTE: add code example from lecture slides

This is a good solution, however it falls apart when we are using Distributed CPU's, the solution to this is using **message passing**.

We can also use **Barriers** in order to solve synchronisation problems, this is the use of signals to wait for multiple threads to complete before we can continue executing on a particular thread.

Readers and Writers

- Multiple readers can access the area at the same time
- Writers require exclusive access
 - All readers need to exit before the writer can gain the lock
 - New readers may arrive while writer is waiting

Is there a better solution to make this system more fair for the writer using Semaphores or Mutex's

Lecture Four - Deadlocks, Starvation and Thread Patterns

We use semaphores such as `mutex`, in order to prevent deadlocks and starvation.

How to make single-threaded code into multi-threaded code

This is reasonably difficult to do, here are some of the issues:

- Local variables are fine; global variables may need to be thread specific
 - Some languages implement `thread_local` declarations (C++)
- Libraries called may not be thread-safe
 - Who consumes signals?
 - Memory access needs to be atomic

- Can be solved via mutual exclusion libraries (locking)
- If they are thread safe, this will be outlined in the man pages
- Kernel processes may not be thread-aware (stacks)

Thread Patterns Dispatcher/worker thread pattern

- Dispatcher thread handles incoming requests and farms out to pool of worker threads
- Workers get woken to perform their task
- Example of this layout is a Web Server

Team/pool

- All team members are equal:
 - wait for incoming requests and grab one to process
- Managed pool: threads in pool created and destroyed by library
- Can be specialised too (running different code)
 - place inappropriate requests into an internal queue (to redirect to other threads)

Pipeline

- Chain of consumer/producers
 - Each thread consumes a request and produces a new one for the next thread
 - Specialised threads designed to minimise latency

pop-up threads

- Thread created when needed to handle new request
 - starts a fresh thread, this is faster than context switching in threads

Lecture Five - Signals and Pipes

Signals Signals are a simple route of communication, that is primarily for exception handling, but there are also signals for other things

- Fixed set of signals (Unix):
 - **SIGINT**: The process is being interrupted; terminates quietly
 - **SIGQUIT**: Forces the process to end and core dump
 - **SIGILL**: FIXME - fill here

- **SIGSTOP**: which stops the process from executing (*This cannot be stopped*)
- **SIGKILL**: which kills the process (*This cannot be stopped*)

Signals are implemented in hardware (division by zero), handled by the OS, (file size limit exceeded), and is primarily handled by the user (via keystrokes)

Other processes such as a child process notifying its parent that it has terminated (**SIGCHLD**), or sending a signal.

- Signal numbers range from {0, ..., 31}
 - We will refer to these signals by name rather than reference code
- uses **PID**: process or processes to receive a signal
- if **pid** = -1: all processes user has permission over
 - Elevated user (*such as sudo or root privileges*)
 - All processes with same user ID
- if **pid** < -1: All processes in *process group*

Multiple types of signals can be handled from one signal handler, **SIGCHLD** signal is sent to a parent process when one of it's child processes terminates.

Signal Overview:

- They do not carry information
- Participating processes must know each others **pid's**

Pipes A pipe is nothing more than a byte stream.

Pipes allows one process to pass information to another process via a **pseudofile**

- One-way queues that the OS kernel maintains in memory
- Guaranteed to provide FIFO delivery of information
- Two types: futher info found here
 - Unnamed pipes
 - * Can only be used between two related processes *child/parent, child/child*
 - Named pipes
 - * Once a named pipe is created, processes can **open()** , **read()** and **write()** them just like any other file. Unless you specify **O_NONBLOCK**, or **O_NDELAY**, on the open: opens for reading will block until a process opens if for writing.

- Pipe properties:
 - synchronised byte stream
 - Operated as a bounded buffer with blocking
 - Each pipe is one-way stream
 - one to one mapping
 - No way to test a pipe for data

Code Example of an unnamed pipe

```
1 #include <stdio.h>
2 #define READ 0
3 /* The index of the "read" end of the pipe */
4 #define WRITE 1
5 /* The index of the "write" end of the pipe */
6 char * phrase = "Stuff this in your pipe and smoke it";
7
8 main ()
9 {
10     int fd[2], bytesRead;
11     char message [100]; /* parent processes message buffer */
12     pipe ( fd ); /* Create an unnamed pipe */
13     if ( fork ( ) == 0 ) /* Child Writer */
14     {
15         close (fd[READ]); /* Close unused end*/
16         write (fd[WRITE], phrase, strlen ( phrase) +1); /* include NULL*/
17         close (fd[WRITE]); /* Close used end*/
18     }
19     else
20     {
21         /* Parent Reader */
22         close (fd[WRITE]); /* Close unused end*/ bytesRead = read ( fd[READ]
23         ], message, 100);
24         printf ( "Read %d bytes: %s\n", bytesRead, message);
25         close ( fd[READ]); /* Close used end */
26     }
27 }
```

Code Example of a named pipe

```
1 /* Writer */
2
3 #include <stdio.h>
4 #include <sys/types.h>
5 #include <sys/stat.h>
6 #include <fcntl.h>
7 char * phrase = "Stuff this in your pipe and smoke it";
8 int main () {
9     int fd1; fd1 = open ( "mypipe", O_WRONLY ); write (fd1, phrase,
10     strlen ( phrase)+1 ); close (fd1);
```

```
10 }
11
12 /* Reader */
13
14 #include <stdio.h>
15 #include <sys/types.h>
16 #include <sys/stat.h>
17 #include <fcntl.h>
18 int main ()
19 {
20     int fd1;
21     char buf [100];
22     fd1 = open ( "mypipe", O_RDONLY ); read ( fd1, buf, 100 ); printf ( "
23     %s\n", buf ); close (fd1);
24 }
```

We can use `popen()` and `pclose()` macro functions in order to create a pipe, fork the child process and invokes the child in the shell and runs command (visit the man pages for more information).

Named pipes in the shell are created by the `mknod()` , `mkfifo()` commands/functions, can be accessed with name permissions.

Opening and closing using the standard `fopen/fclose`, each pipe is used as a buffer.

Lecture Six - Sockets

Stream Sockets	Datagram Sockets
TCP	UDP
reliable delivery	unreliable delivery
In-order guaranteed	no order guarantees
connection-orientated	no notion of a connection
bidirectional	can send or receive

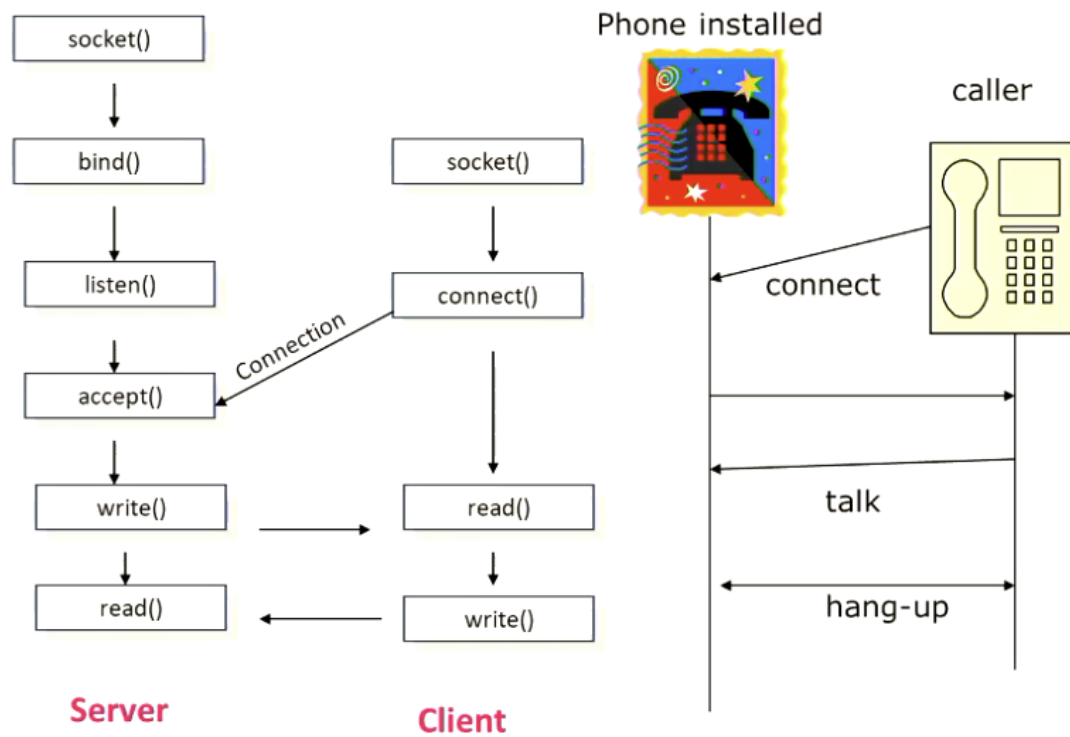

Figure 9: Phone Example: socket streams

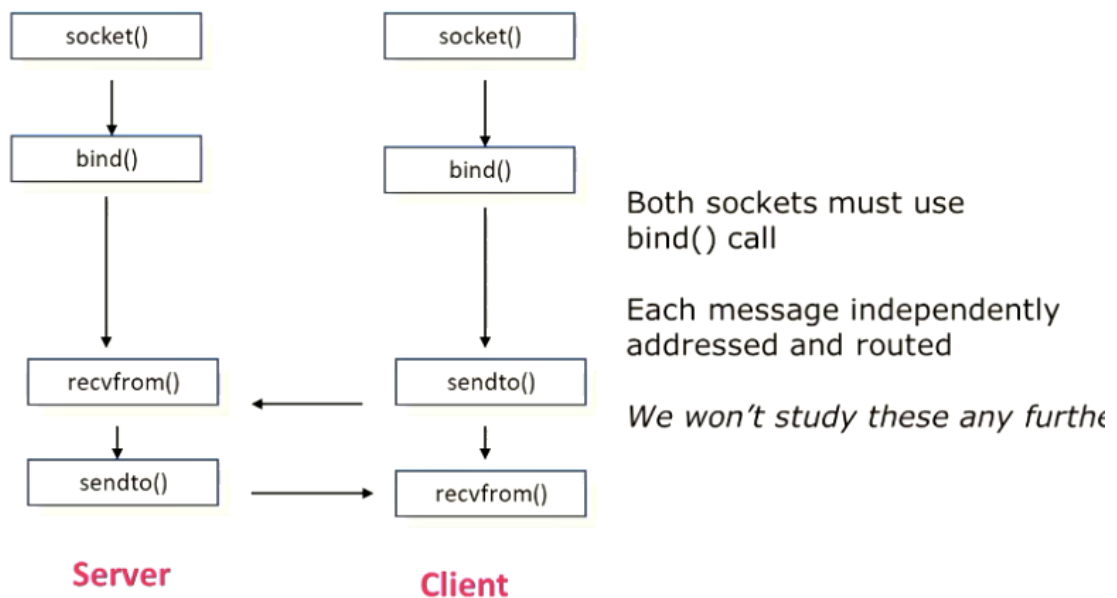

Figure 10: Datagram Example: socket streams

Note this will not be locked at further, we will focus mostly on Socket streams (TCP)

Networking basics

- Application layer
 - Standard applications
 - User applications
- Transport layer - we will be looking at this more in-depth
 - TCP
 - * Connection orientated
 - * Provides a reliable flow of data between systems
 - UDP
 - * Clock server
 - * Ping
 - Programming interface

* Sockets

- Network layer
 - IP
- Link layer
 - Device drivers

Webb protocols and services

- All resources are identified by a URL, the URL has four parts
 - Protocol
 - Host
 - Port
 - Resources
- Applications can refer to destination by name rather than IP
- Within the communication domain sockets are referred to by address

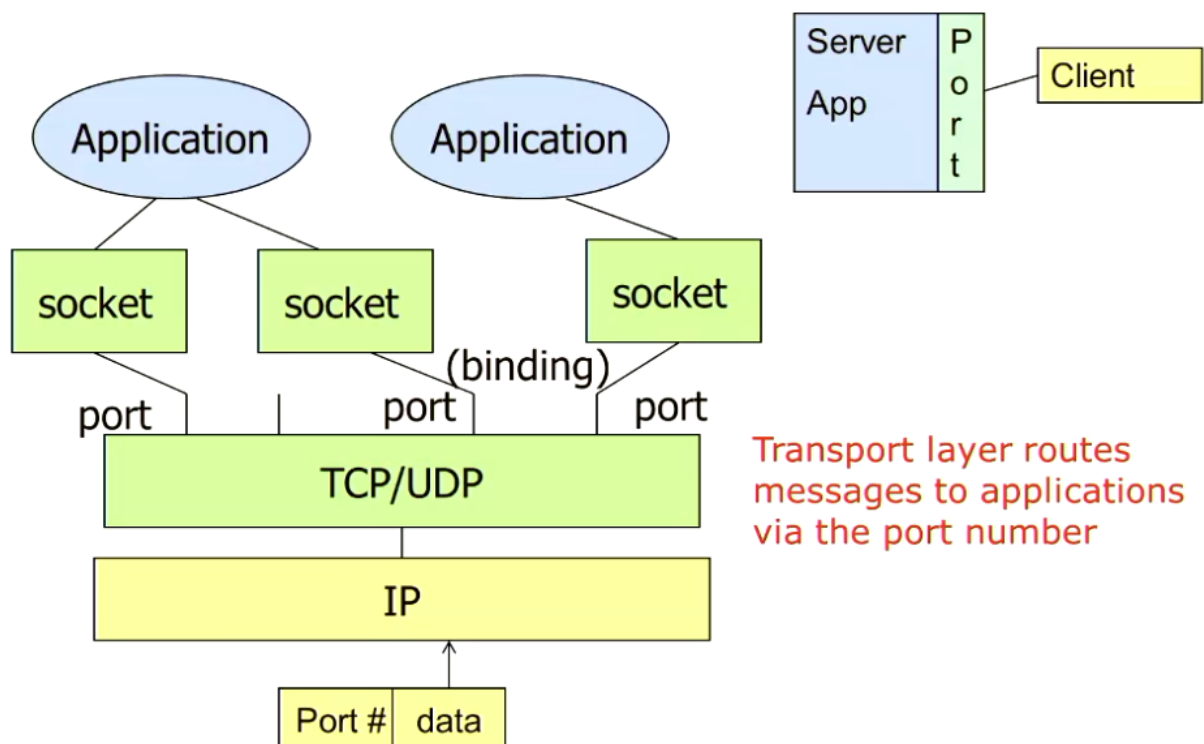

Figure 11: Sockets and ports

Establishing a connection

1. Client sends a request to the server by hostname and port number
2. Server accepts the connection, creating a new socket bond to a different port
 - Common to service the actual connection in a separate thread/process
3. The original server port is again ready to listen for other connection requests
 - We use Big Endian with networking byte order

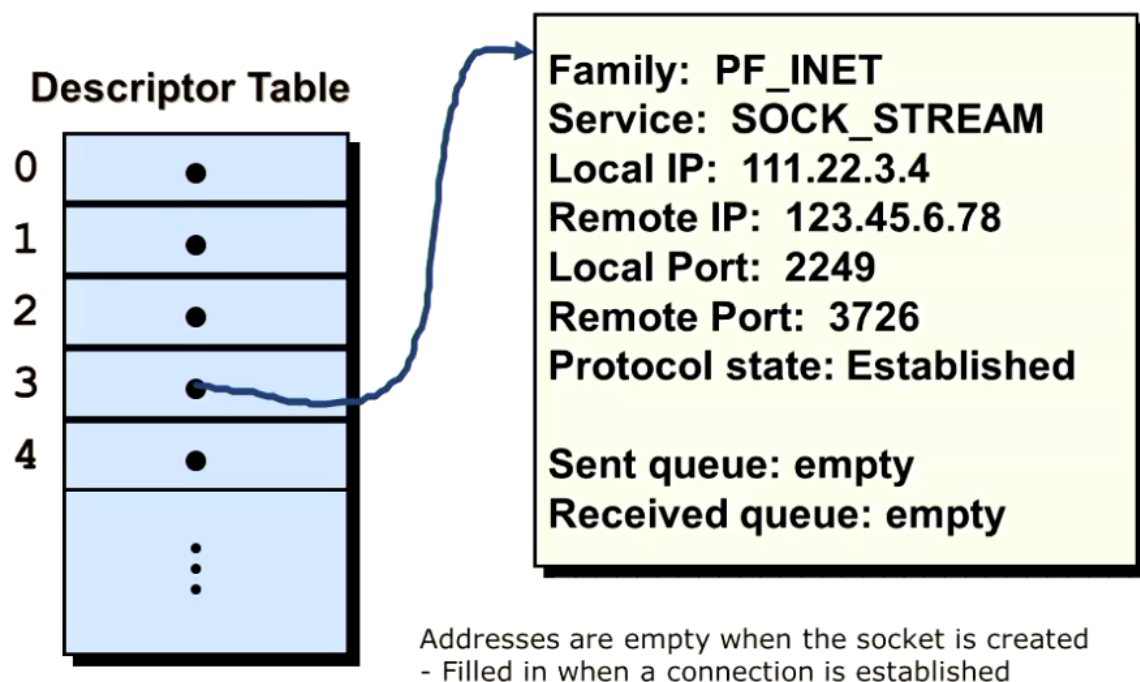

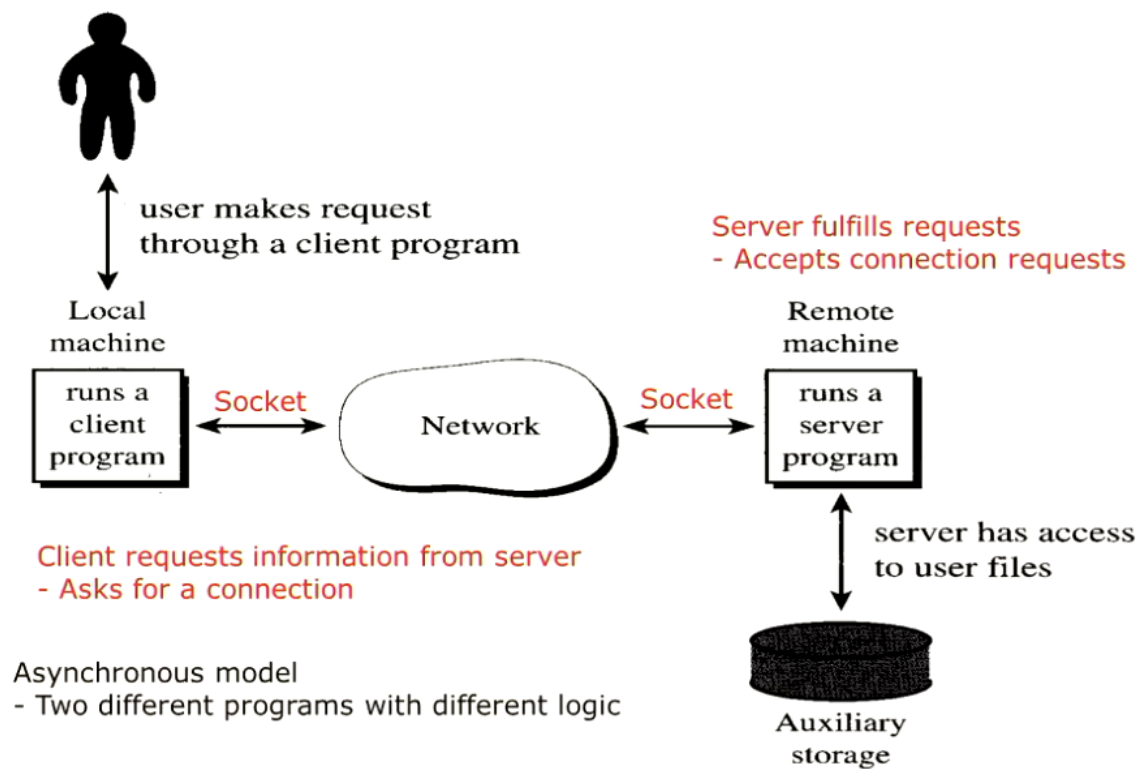

Figure 12: Socket descriptor and data structure

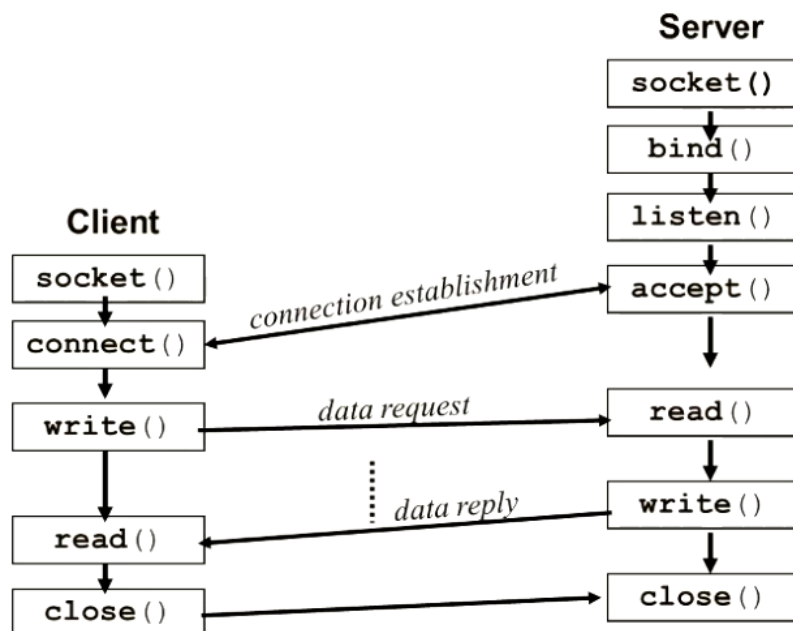

Figure 13: Client, Server model

Next week we will delve into the code for this part of the course

Lecture Seven - Socket Coding

Simple Socket Client

```
#include <stdio.h>
#include <stdlib.h>
#include <netinet/in.h>
#include <sys/socket.h>

int main() {

    int client_socket = socket(AF_INET, SOCK_STREAM, 0);    Create socket

    struct addrinfo *server_address = NULL;
    struct addrinfo hints;
    memset(&hints, 0, sizeof(struct addrinfo));
    hints.ai_family = AF_INET;
    hints.ai_socktype = SOCK_STREAM;
    getaddrinfo( "localhost", "1234", &hints, &server_address);
    connect(client_socket, server_address->ai_addr, server_address->ai_addrlen);

    Send connection request to server address

    char data[512] = {'\0'};
    int message_length = sprintf(data, "hello server");
    message_length = write(client_socket, data, message_length);
    message_length = read(client_socket, data, 512);
    printf("from server: %s\n", data);

    Communicate

    close(client_socket);    Close socket

    return 0;
}
```

Figure 14: Simple socket client

```

#include <stdio.h>
#include <stdlib.h>
#include <netinet/in.h>
#include <sys/socket.h>

int main() {

    int server_socket = socket(AF_INET, SOCK_STREAM, 0); Create socket

    struct sockaddr_in server_address, client_address;
    server_address.sin_family = AF_INET;
    server_address.sin_addr.s_addr = INADDR_ANY;
    server_address.sin_port = htons(1234);
    bind(server_socket, (struct sockaddr *)&server_address, sizeof(struct sockaddr_in)); Bind to address, port

    listen(server_socket, 5); Listen for a request

    socklen_t l = sizeof(struct sockaddr_in); /* client address length */
    int client_socket = accept(server_socket, (struct sockaddr *)&client_address, &l); Accept request

    char data[512] = { '\0' };
    int message_length = read(client_socket, data, 512);
    printf("from client: %s\n", data);
    message_length = sprintf(data, "back to ya client");
    message_length = write(client_socket, data, message_length); Communicate

    close(client_socket); Close socket

    return 0;
}

```

Figure 15: Simple socket server

This lecture just goes over the code seen above and further examples, for further details on what this code does, consider visiting man pages or watch the lecture while implementing (this is reasonably familiar, however if I am battling to understand, refer to the lecture).

Socketaddr

Three different types of sockaddr:

- Unix Domain sockets
- Generic address
- Internet domain sockets

Lecture Eight - Scheduling

Introduction to scheduling

- How to schedule a mixture of process behaviours?
- How to best use resources?

- What are we trying to optimise?
- How are we going to make it fair?

Systems and process types

- Nonpreemptive: Every job runs to completion
- Preemptive: Jobs can be interrupted

System types and scheduler requirements

- Batch
 - No users waiting
 - Nonpreemptive
- Interactive
 - User waiting
 - User workstations/devices and servers
 - Preemption is essential
- Real-time
 - Dominated by periodic and need to meet deadline
 - Process designed in advance to work together
 - Can be nonpreemptive or preemptive depending on load

Scheduling goals and policy

All systems:

- Fairness
- Policy enforcement: seeing that stated policy is followed
- Balance: Keeping all parts of system busy

Batch systems:

- Throughput maximising
- Turnaround time (minimise)
- CPU utilization

Interactive systems:

- Response time
- Proportionality

Real-time systems:

- Meeting deadlines
- Predictability

Scheduling in batch systems

- Requires knowledge of job lengths
- Nonpreemptive
 - Assumes some jobs arrive at the same time so can choose
- Preemptive: shortest time to complete next
 - Allows new short jobs to interrupt longer ones
- Sometimes we use *First come first served (FCFS)* or *shortest job first (SJF)*

Incorporating I/O

- Each CPU burst treated as a new job
- Long job fills I/O

Interactive Schedulers

Very complex

Some solutions:

- Round-robin scheduling (*simple solution*)
 - Preemptive switch every m seconds
 - Assumes *equal importance*
 - Can be dominated by process switching time
- Priority scheduling with multiple queues
 - Each queue only runs when higher empty
 - Round robin scheduling of each level
 - Lower queues can starve
 - * Answer: dynamic priority allocation
 - Dynamic scheduling:
 - * New jobs start with highest priority
 - * Job using up its time slice downgraded
 - * Job *not* using time slice stays the same
 - * Essentially light tasks go to top, heavy CPU tasks go to bottom
 - * A better method is to replace rules two and three do downgrade based on how much CPU has been used (*# of slices*), neutral strategic I/O

- Further tuning strategies
 - * Increase time period for lower priority jobs
 - * Calculate *ad hoc* priority based on past job times, weighted sum decaying over time

$$T = \frac{(T_0 + T_1)}{2}$$
 - * User hints
 - * Scheduler parameters
- Shortest process next
- Guaranteed scheduling
- Fair-share scheduling

Schedule fairness

- Allocate CPU time per *user*, not per process
- Track CPU usage and schedule accordingly
- Lottery scheduling:
 - Each user given $\frac{1}{n}$ tickets (priority adjusted)
 - Distribute amongst processes
 - Randomly select a ticket and schedule the owning process
 - Can give tickets away
 - * e.g. client to server process

Real-time scheduling

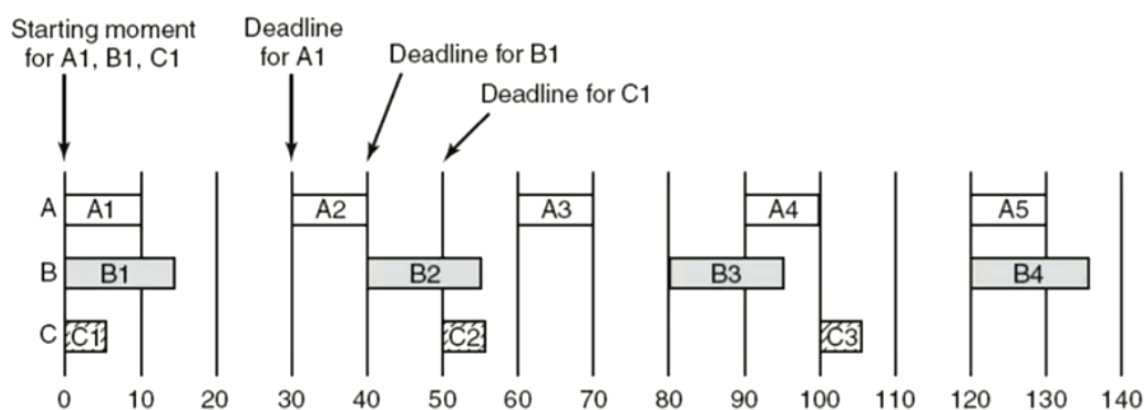

Figure 16: Real time scheduling

- Example: multimedia server
 - Different periodicity (deadline) and processing time requirements

- How to schedule so deadlines always met?

Rate monotonic scheduling

- Priority = $1/\text{deadline frequency}$
- Always runs highest priority process
- strict conditions:
 - Each process completes within period
 - No inter-process dependencies

Earliest deadline first

- Process with earlier deadline preempts the current process
 - Relaxes the constant frequency requirement

Note that RMS is load-dependent, EDF always works but we have to calculate deadlines (more complex)

Policy vs Mechanism

Separate what is allowed to be done with how it is done

- A process knows which of its children threads are important and need priority
- Scheduling algorithm parameterized
- Parameters filled in by the user processes
