
Web Computing Architecture

This course explores web applications and the underlying distributed application architectures and technologies. Topics will include web fundamentals (HTML, HTTP, CSS, JavaScript), asynchronous events, data persistence, web application architectures, AJAX, web APIs, and web computing.

Jordan Pyott

Course Information

Grading Structure

- Assignment One (25%)
 - No extension
- Mid-semester test (20%)
 - Wednesday 24 March, 7:00 pm
 - Topics
 - * HTTP
 - * REST API
 - * JavaScript
 - * Web databases
 - paper exam, closed book
 - 24 short answer questions
 - 2 hours (should take less)
- Assignment 2 (25%)
 - Compulsory lab in final week
 - No extension
- Exam (30%)
 - 2 hours

Labs

Lectures

Lecture One: Introduction to HTTP and JavaScript

What is a web application?

- Uses HTTP server to interact
- Runs in a web-browser
- Generally interacts with a server back-end

We will be using a restful approach to building our JavaScript web application's.

Here is how we will structure a web-app

structure

In *Assignment One* we will need to do the following

- Create HTTP server + application
- HTTP requests and response cycle
- URL e.g. protocol, path, endpoints, query parameters
- HTTP headers and body
 - Headers: e.g. using Cookies
 - Headers: e.g. CORS
 - Body e.g. JSON data
- HTTP methods e.g. GET, PUT, DELETE
- HTTP status codes e.g. 201, 404
- Authentication and authorization
- Asynchronous requests
- Database connectivity
- Conform to API specification
 - You will be given an API specification to implement

NOTE: When we do the assignment we will all be assigned a port number to connect to on the test server

In *Assignment Two* we will need to do the following

HTTP Client

- HTML + CSS + JS app
- Modern browser
- Implementing user story backlog
- Authentication and authorization
- Asynchronous requests
- RESTful API calls

HTTP messages are how data is exchanged between the server and the client, there are two types of messages: *requests* sent by the client to trigger a *response* from the server.

HTTP messages are composed of a textual information encoded in ASCII, and span over multiple lines. In HTTP/1.1 and earlier versions of the protocol, these messages were **openly** sent across the connection.

Uniform Resource Identifiers (URI's)

- A string of characters to identify (name, or name and location) resource.
- A URL is a URI that also specifies the means of acting upon or obtaining representation
- A URN is a historic URI term that has since been depreciated
- The HTML path is increasingly becoming an abstraction as unlike an HTML path, the ever more growing language JavaScript does not show the local path, and instead uses a server to generate the html that is being used to pass parameter calls for functions, id numbers, versioning information etc.

Anchors

- Anchors are used as bookmarks within a classic HTML file.

NOTE: There are many JS libraries to achieve the above functionality, we will mostly be implementing these libraries rather than building this functionality from scratch.

As well as the URL, there are HTTP headers:

- General headers: required and additional
- Entity headers: applies to the body of the request
- Request headers
- Response headers
- Cookies are implemented within the header using `set-cookie: <...>`

We use headers and cookies in order to:

- Maintain session
- Personalise
- Track data (e.g. advertising)

Header structures

Structure and example of HTTP requests

HTTP-method SP Request-URL SP HTTP-Version CRLF

Request body...

Example GET request

```
GET /pub/blah.html HTTP/1.1
HOST: www.w3.org
```

Body of post (e.g. form fields; this is usually in the form of JSON data)

HTTP Responses

HTTP-Version SP Status-Code SP Reason-Phrase CRLF
Response body

Successful response (GET/POST)

HTTP/1.1 200 OK
Data: Mon, 04 Jul 2011 06:00:01 GMT
Server: Apache
Accept-Rangers: bytes
Content-Length 1240
Connection: close
Content-Type: test/html; charset=UTF-8

<HTML body>

Response Codes

- 1xx: Informational issues
- 2xx: Success
- 3xx: Redirections
- 4xx: Client error
- 5xx: Server error

We will be using the Express Package in order to build our server, this will allow us to listen for requests on an endpoint, below is a diagram of how this might work:

Express structure

The body of an HTTP request

- Three types of body data:
 - Single resource bodies: consisting of single file of known length, defined by the two headers Content-Type and Content-Length.
 - Single resource bodies: consisting of sing files of unknown length, encoded using chunks with Transfer-Encoding.

- Multiple-resource bodies: consisting of multipart body, each containing a different section of information. These are relatively rare.

There are a number of HTTP verbs:

1. GET
2. PUT
3. POST
4. DELETE
5. HEAD
6. PATCH

REST (Representational State Transfer)

REST is a way for developers to use HTTP methods/verbs explicitly and consistently with the HTTP protocol definition. REST and CRUD are used together, rest implies that we should only use these HTTP verbs ONLY when we want to implement CRUD, we should not use these verbs for other tasks, REST implies that it is bad practice to use HTTP methods in unconventional ways.

JavaScript Introduction JavaScript has the following things

- Objects, methods and functions
- Expressions, statements and declarations
- Functions
 - Immediately invoked function expression
- Scoping issues
- Variables and (variable hoisting)
- Closures
- this keyword
- Method chaining (cascading)
- use `strict` mode
- Modularisation: export and require
- Node.js
- Asynchronous (event) handling
 - Callbacks, Promises Async/Await

JavaScript is object orientated, however it is not strictly OOP

- An object is a collection of properties and a property is an association between a name or key and a value

- A property can itself be an object
- A method is a function associated with an object or alternatively a method is a property that is a function
- Functions are first-class objects
- They can have properties and methods, just like an other object
- Unlike other objects, functions can be called
- Functions are, technically, function objects
- Functions can be called like a lambda function by putting () around the whole function
- Functions can be unnamed

Expressions, statements and declarations

- An expression produces a value
- A statement does not return a value
- Declarations are creations of new things
- JavaScript also has
 - Expression statements: where it expects a statement you can also write an expression
 - The reverse does not hold: you cannot write a statement where JavaScript expects an expression

Example of this in implementation:

```
var result = function aFunction () {  
    return -1  
}
```

This will assign result = aFunction(), it is NOT equal to -1 (in this case it is because there is no parameter being passed)

To execute a function immediately we can call it using the following syntax

```
+function functionName () {  
    console.log('Hello, World!')  
} (); // These end brackets call the function immediately defined above
```

Anything defined within a function is within its scope, nested functions will contain the same scope as the outer function.

IMPORTANT NOTE: Functions will use the scope of where they are declared, not where they are called or implemented.

Using the following code will avoid these idiocies as they are blocked scoped:

```
let x = 1;  
const y = 2;
```

Use this keyword carefully, it references different objects depending on the context it is implemented in:

- In a browser it references the window
- in node.js it references a global object
- and in other context it works differently

Chaining functions can make your code more readable.

Lecture Two: Asynchronous behaviour

A problem that we commonly face is when we have some set of actions, but we do not know in what order these tasks/actions are going to be completed in. JavaScript is a single threaded language, it has a single call stack, a heap and the message queue which records a list of messages to be processed and the associate callback functions to execute.

It also has an event loop, this is the order of operations the heap is called in, understanding this is crucial to understanding odd errors that may occur.

The term Blocking really just means, we don't want to fill the call stack, when we have blocking code in JS it is just when the call stack is too full (a while loop if it is not running too long will not be blocking)

We need to structure our code into different modules, there are different ways of managing this. Modular JavaScript files, we will be using the CommonJS approach.

CommonJS:

- One specification for managing module dependencies
- maps well to Node.js

We can use the `require()` function in order to use local modules, and we are able to install external modules using the Node Package Manager (npm) *commands - install, upgrade, status, -v*

```
// Syntax for require function  
var importJson = require("./path/to/data.json");
```

We will use the express library as a public interface module to use the web.

Lecture Three: data persistence with SQL, memory stores and Graph DB

Using JSON data

- JSON is a lightweight data-interchange format

- A syntax for serializing data, objects, arrays, numbers, strings
- Data only, does not support comments except as a data field
- Non specific to JavaScript
 - Was originally intended for data interchange between Java and JavaScript
- No versioning for JSON
 - Enables consistency
 - Data gets updated all the time, it means that the syntax will always remain stable
- JSON has many variants (maintained by different people)
 - JSON-T (template JSON)
 - Many other forms of JSON
- JSON rules:
 - All key-names are double-quoted
 - Values
 - * Strings are double quoted
 - * Non-strings are not quoted
 - Escape uses
 - Works with a set of values contained (can be mapped to a large dictionary)

Relational Databases

- One of the few situations where a theoretical contribution led to use case in the industry
- Relational Model
 - Data is presented as relations
 - Collections of tables with columns and rows (tuples)
 - Each tuple has attributes
 - Unique key per row
 - Relational model is built off of Relational Calculus (formal notation of key points)
- ACID transactions
 - Atomicity: if one part of a transaction fails, then transaction fails
 - Consistency: the database is kept in a consistent state before and after transaction execution
 - isolation: one transaction should not see the effects of another in progress
 - Durability: ensures transactions, once committed, are persistent

CAP Theorem

- In distributed computing, choose two of:
 - Consistency - every read receives the most recent data
 - Availability - every read receives a response
 - Partition tolerance - system continues if network goes down
- Situation is actually more subtle than implied
- BASE
 - Give up consistency and instead get:
 - * Basic Availability - through replication
 - * Soft state - state of the system may change over time
 - * Eventual consistency - the data will be consistent eventually

Memory Data Store

- Whole database stored in RAM
 - Very fast access
 - Useful for cached storage
- Key value store where the value can be complex data structure
 - Strings, Bit arrays, lists, sets, hashes
 - streams
 - binary safe keys
 - command set for optimized load, storing and changing data values
- Useful for logging

Document Databases

- Storing in local files (JSON/XML or any other unstructured data format)
- Tends to be stored with meta data (security, providence)
- Builds index from contexts and meta data
- storage of raw program types
- Complex data easily stored
- No need for costly schema
- Same data can be replicated (loads of redundancy)

Graph Databases

- Nodes: represent an entity
- Edge: represents relationship between nodes

- Properties: describe attributes of the node or edge
- Hyper graph: one edge can join multiple nodes

Lecture Four: REST

A REST service has the following benefits

- Platform independent
- Language independent
- Standards based (runs on top of http)
- Can easily be used in presence of firewalls
- RESTful systems typically
 - communicate over HTTP
 - with the same HTTP verbs (GET, POST, PUT, DELETE)
- Use URL to navigate between the API instances

Lecture Five: GraphQL and automated API testing

Note that for the assignments that we are assigned within this course, the local port servers will be hosted via your local computer (and a database that is port forwarded through the university), this is different from the test server as the test server is set up using a docker container on a virtual machine with a series of automated tests run on a server. This is what allows us to build on the eng-gi t server with automated testing.

You can run the tests via local host if we change the deploy address to `localhost:9499` or whatever the local port that is allocated.

Differences between the logic on the server and localhost

1. Why can your local HTTP server pass your postman tests and fail the automated server tests?
2. What problems arise when you use automated testing on the testing server

These happen because of the raw number of requests that are being run onto the local my SQL services. This is just a factor of how the University has the testing server set up.

Here is a diagram for how the API specification manages requests to the test server:

Testing Server Structure

Example of formatting routes for an HTTP request from `users.routes.js` This is responsible for directing the endpoints to get the correct information for an end user

```
const users = require("../controllers/users.controller");
```

```
module.exports = function (app) {  
  app.route(app.rootUrl + "/users/login").post(users.login);  
  app.route(app.rootUrl + "/users/logout").post(users.logout);  
};
```

Here is an example of a controller for an HTTP Request from `users.controller.js`. This is where we handle all the logic for the request, checking inputs from the request and then gets the SQL request from the model and then returns the response to the user routes

```
const users = require("../models/users.model");  
const tokenCreate = require("rand-token");  
const passwords = require("../passwords");  
const bcrypt = require("bcrypt");  
  
exports.login = async function (req, res) {  
  try {  
    const email = req.body.email;  
    const password = await passwords.hash(req.body.password);  
    const token = tokenCreate.generate(32);  
    if (  
      !email.includes("@") ||  
      email == undefined ||  
      email.length < 1 ||  
      password == undefined ||  
      password.length < 1  
    ) {  
      res.status(400).send(`ERROR: Bad Request`);  
    } else {  
      const response = await users.loginAccount(email);  
      if (response == null) {  
        res.status(400).send(`ERROR: Bad Request`);  
      } else if (  
        (await bcrypt.compare(req.body.password, response.password)) ==  
        ↪ false  
      ) {  
        res.status(400).send(`ERROR: Bad Request`);  
      } else if (  
        (await bcrypt.compare(req.body.password, response.password)) ==  
        ↪ true  
      ) {  
        await users.setToken(token, response.id);  
        res.status(200).send({  
          userId: response.id,  
        });  
      }  
    }  
  }  
}
```

```
        token: token,
      });
      return token;
    }
  }
} catch (err) {
  console.log(err);
  res.status(500).send(`ERROR: Internal Server Error`);
}
};

exports.logout = async function (req, res) {
  try {
    const token = req.header("X-Authorization");
    if (token == null || token == undefined) {
      res.status(401).send(`ERROR: Unauthorized`);
    } else {
      const response = await users.logoutAccount(token);
      if (response[0].affectedRows == 0) {
        res.status(401).send(`ERROR: Unauthorized`);
      } else {
        res.status(200).send();
      }
    }
  } catch (err) {
    console.log(err);
    res.status(500).send(`ERROR: Internal Server Error`);
  }
};
```

Here is an example of the model code for an HTTP request, this is responsible for making the request to the SQL database.

```
const db = require("../../config/db");

exports.loginAccount = async function (email) {
  try {
    const post = `select email, password, id from user where
    ↪ email='${email}'`;
    const conn = await db.getPool().getConnection();
    const [[response]] = await conn.query(post);
    conn.release();
    if (response == undefined) {
```

```
        return null;
    }
    return response;
} catch (err) {
    return null;
}
};

exports.logoutAccount = async function (token) {
    const update = `update user set auth_token=null where auth_token
    ↪ = '${token}'`;
    const conn = await db.getPool().getConnection();
    const response = await conn.query(update);
    conn.release();
    return response;
};
```

Overfetching

- You might download more information than you need

Underfetching

- You request less information that you need
- making multiple small requests when we could have made one larger request at less cost

GraphQL

GraphQL is a *specification* for how you specify data (strong typing) and how you go about querying that data.

There are some reference implementations of GraphQL specification found at here: [GraphQL JavaScript Specification](#)

When using GraphQL A query returns a 200 response code even if the request errors out. Errors are returned in user-defined fields, however Network errors can still return 500 and 400 error codes.

- GraphQL does not require you to think in terms of graphs
 - Though relational tables are useful for understanding
 - You think in terms of JSON Objects for a query
- Is not querying the database directly
 - Rather is a language specification for composing queries to a server
- Still requires some kind of pre-defined data and queries on the server-side

- Objects, fields and allowable queries
- But these pre-defined are more atomic in their nature

Chai and Mocha are two testing frameworks for JavaScript that we will be using in this class.

We should use an Asynchronous approach for when we are creating testing:

- Mocha, Chai and Chai-HTTP can handle callbacks, Promises and async/await
- Don't get these mixed up in a given test
 - Avoid the use of `return` together with `done()`

Examples of defined tests can be found here: Lecture timestamp: 1:15:55

The testing framework has similar testing functions to those seen in Jest:

- `beforeEach()`
- `before()`
- `after()`

More information can be found in the documentation with Chai and Mocha testing.

Lecture 6: Security and Introduction to Web Clients

Note, incorporating security on an advanced level is not in the scope of the course, the content covered here is more of a primer to encourage you to do your own reading of security content.

OWASP: The Open Web Application Security Project

This is an open source project that is about how to deal with security in web development, further can be found on the OWASP website, but here is a summary.

Top 10 Security issues

Injection

Broken Authentication

Sensitive Data Exposure

Broken Access Control

XML External Entities (XXE)

Security Misconfiguration

Cross-Site Scripting (XSS)

Insecure De-serialization

Using Components with Known Vulnerabilities

Insufficient Logging and Monitoring

Note: Some of these topics will be explained later throughout the course

One method to validate a field is to validate and re-validate.

An input field is likely to be validated on the client side, that an IDNumber text field contains a number rather than a number on a malicious piece of code

Definitions:

- **Authentication:** Establish claimed identity
- **Authorisation:** Establish permission to act

We need to authenticate before we authorise a user. Authenticating a user means to check if the user is valid, i.e. *correct user name and password*, to authorise a user means to have the correct permissions i.e. *user is an administrator*

The bare minimum for a secure network is to use HTTPS (the HTTP protocol with SSL)

Steps to securing:

- Verify architecture
- Verify the implementation

- Follow guidelines from OWASP

Note: JavaScript + Node does NOT EQUAL JavaScript + browser

When dealing with JavaScript in the browser, you are dealing with the user, client side with indirect input and output via HTML + CSS and the DOM, when using JavaScript on the server side, we are interacting with inputs and outputting responses to the front end data. *Another thing to realise is that a large number of npm packages won't work in your browser.*
